Abstract

Introduction: Tubeless percutaneous nephrolithotomy (PCNL) is the non-placement of a nephrostomy tube at the end of the procedure. The benefits of a nephrostomy tube placement are numerous as it provides adequate renal drainage. It may also tamponade bleeding and allow for an easier second-look nephroscopy. However, these advantages are mostly theoretical, and the majority of authors consider the nephrostomy tube as a source of morbidity.

Objectives: The aim of this report was to study the efficiency, safety, and morbidity of tubeless PCNL by comparing it to the standard technique.

Methods: This is a unicentric retrospective study of 125 patients who had undergone PCNL for renal lithiasis. We divided the patients into two groups: the standard PCNL group (n = 74) and the tubeless PCNL group (n = 51). The rates of good outcomes, complications, duration of hospitalization, and the degree of postoperative pain were compared between these two groups.

Results: There were no statistically significant differences between the two groups in age, gender, history, and the number of stones treated. There were more staghorn stones in the PCNL group with nephrostomy (p = 0.007) and more pelvicalyceal stones in the tubeless group (p = 0.037). Patients who had the standard PCNL had larger stones (p = 0.008). Patients who had a tubeless PCNL had more postoperative infectious complications than the standard PCNL group (p = 0.042). No statistically significant differences were noted for other complications, good outcomes (p = 0.13), postoperative pain (p = 0.51), and duration of hospitalization (p = 0.16).

Conclusion: According to the majority of authors, tubeless PCNL is considered a safe and efficient technique. It also provides advantages with less postoperative pain and duration of hospitalization. We believe that a selection bias may exist in most published work concerning routine nephrostomy tube placement.

Introduction
The treatment of urolithiasis and endourology has been revolutionized with the advent of modern and minimally invasive techniques. Percutaneous nephrolithotomy (PCNL) represents an important advance that significantly reduces the number of lumbotomies performed for benign lithiasis [1]. The concept of percutaneous tubeless nephrolithotomy was to no longer put a nephrostomy tube at the end of the procedure and to drain the renal cavities only with a ureteral stent [2].

Through this work, our aim was to study the effectiveness, safety, and morbidity of tubeless PCNL by comparing it to the standard technique.

**Materials And Methods**

We retrospectively analyzed data from 125 patients who had undergone PCNL in our Urology Department between January 2015 and December 2017.

In our study, we included patients of both sexes over the age of 18 years in which the renal cavities were not perforated perioperatively. Patients with a single kidney or a congenital malformation and in whom more than one caliceal puncture was performed were excluded. No patient had a supracostal puncture or bilateral PCNL. All patients had a preoperative computed tomography urography (CTU) (a non-injected CT scan in patients with impaired renal function) and negative urine culture. All PCNLs were performed under general anesthesia in the Galadakao-modified supine Valdivia Uria position.

The patients were divided into two groups:

- **Group 1** (standard PCNL) \(n = 74\) in which the renal cavity drainage was provided by a nephrostomy tube (Fr 18) and a double-J ureteral stent or ureteral catheter.

- **Group 2** (tubeless PCNL) \(n = 51\): No nephrostomy was performed and a double-J catheter was kept in for one month.

PCNL results were considered good in the absence of residual lithiasis or less than 5 mm residual stones. We considered bleeding as a major complication when a blood transfusion was needed. We evaluated postoperative pain by the usage or non-usage of opioid analgesics.

Age, medical history, PCNL efficacy, specific and nonspecific complications, postoperative pain, and duration of hospitalization were compared between the two groups.

**Statistical analysis**

Average comparisons in two independent series were performed using Students T-test. Pearson's Chi-square test was used to compare percentages in independent series. The significance level was set at 0.05.

**Results**

The clinical and demographic characteristics of our patients are detailed in Table 1. No statistically significant differences were noted between the two groups regarding age, sex, medical history, creatinine clearance, and prior surgery for lithiasis or shock wave lithotripsy (SWL).
Regarding the treated stones (Table 2), it was found that there were more staghorn stones in the PCNL group with nephrostomy ($p = 0.007$) and more pelvicalyceal stones in the tubeless group ($p = 0.037$). Patients who had standard PCNL had larger stones ($p = 0.008$) with no statistically significant difference between the two groups regarding stone numbers ($p = 0.14$).
TABLE 2: Characteristics of Treated Stones

PCNL: percutaneous nephrolithotomy

No statistically significant difference was found between our two groups concerning the effectiveness of the PCNL (p = 0.13). Patients who had a tubeless PCNL had more postoperative infectious complications than the standard PCNL group (p = 0.042). No statistically significant differences were noted for other complications, postoperative pain (p = 0.51), or length of hospital stay (p = 0.16) (Table 3).

### TABLE 3: Complication Rate, Length of Hospital Stay, and Degree of Postoperative Pain

PCNL: percutaneous nephrolithotomy; PRBCs: packed red blood cells; SWL: shock wave lithotripsy

### Discussion

Tubeless PCNL was introduced by Bellman in 1997 which consisted of performing a PCNL without nephrostomy drainage at the end of the procedure [3-4].

A literature review confirms that this alternative is safe, effective, and reduces postoperative morbidity and length of hospital stay [2, 5-6], even in obese patients [7], after a supracostal puncture [8], and in patients presenting with large stones [9].

There is currently no consensus on the need for post-PCNL drainage, size and number of nephrostomy catheters (large or small, single or multiple), and type of ureteral drainage (ureteral catheter, double-J, mono-J, no drainage). This choice will often depend on the outcomes and difficulties encountered during the procedure and the surgeon’s habits [10].

In our series, tubeless PCNL was performed in the absence of purulent retention, residual fragments, or significant bleeding. Good outcomes, as well as the rate of perioperative and postoperative complications, were similar to those of standard PCNL, apart from infectious complications which were more present in the standard PCNL group. Our results are consistent
with those observed in almost all published series, except for the infectious complications [2, 5-6, 9].

However, unlike most authors, we did not find a statistically significant difference between the two techniques regarding postoperative pain and length of hospital stay.

According to a number of studies, whether or not a nephrostomy catheter was used depended essentially on the surgeon’s choice, the outcome, and the difficulties encountered during the procedure (Table 4).

Lu et al. (2012) [14]

Prospective randomized: 16 mini-PCNL (+ nephrostomy) versus 16 mini-PCNL tubeless

PCNL tubeless: Shorter hospital stay, less postoperative pain

Groups; (Among inclusion criteria: stone < 4 cm)

81.3%); Explained by: less operative difficulties, surgeon's experience, stone characteristics (Size < 4 cm, site not mentioned)

Zhao et al. (2016) [15]

Prospective randomized: 15 patients: PCNL with nephrostomy without ureteral stent; 15 patients: PCNL without nephrostomy with ureteral stent

Nephrostomy group: More postoperative comfort. No difference concerning complications, length of stay, and postoperative pain.

2 randomized groups; Tubeless: No residual fragments

Selection of patients: 100% stone-free. Patients felt more discomfort with ureteral stents than with a nephrostomy catheter

Jiang et al. (2017) [16]

Prospective randomized (90 patients): 30 PCNL (+ nephrostomy only); 30 PCNL (+ ureteral catheter only); and 30 PCNL (+ JJ stent only).

PCNL (with nephrostomy only): Longest hospital stay and more postop pain than other two groups; PCNL (+ JJ stent): More discomfort.

Randomized study; Selection criteria: stone < 2 cm, no bleeding, no residual calculi, no renal cavity perforation

Selection bias: Small stones, easier to treat - Fewer complications and perioperative difficulties.

### TABLE 4: A Sample of Published Series Comparing Standard PCNL Versus Tubeless

PCNL without nephrostomy drainage is usually performed in the absence of residual fragments and perioperative complications, as well as in patients who are not considered at risk of complication [5, 11-13].

Several authors who studied tubeless PCNL included relatively easily treatable stones in regards to size, number, and site [11, 13-17].

Many authors compared the efficiency of conventional and tubeless PCNL based on the stone-free rate and the size of the residual fragments, whereas it seems to us that whether or not a nephrostomy catheter is placed at the end of the procedure has no direct relationship with the fragmentation and extraction of stones.

Regarding the length of hospital stay, which is shorter in the tubeless PCNL group according to the majority of authors [9, 15, 18], longer hospital stays in the standard PCNL group may be the consequence of restricted selection criteria within the tubeless group. There is no reason for nephrostomy catheter placement to delay the patient’s discharge when its removal only takes a few minutes.

Postoperative pain has aroused the interest of most studies dealing with tubeless PCNL. It is agreed upon that the nephrostomy catheter is a source of postoperative pain [2-3, 17, 19]. However, is the pain caused directly by the catheter’s irritation? Weren’t the factors which led to the nephrostomy placement involved in the genesis of postoperative pain? Does the ureteral stent participate in the patient’s discomfort as well [16]?

In prospective randomized studies, the choice to drain or not by a nephrostomy catheter by a
surgeon whose tendency was to perform tubeless PCNL largely depended on the outcomes, difficulties, and complications encountered [20-23].

In fact, we believe that the slightest complication or procedural difficulty will motivate the surgeon to place a nephrostomy catheter in order to have a wider security margin. This selection bias may falsely confirm the results observed with the tubeless PCNL studies, which remain largely dependent on the surgeon’s experience and habits, as well as the inclusion criteria of the published series.

In our opinion, selection bias exists in most tubeless PCNL studies (Table 4). We believe that nephrostomy drainage at the end of the procedure offers more security for the patient and reduces the risk of complications which can be sometimes fatal.

Conclusions
The majority of authors agree that tubeless PCNL is a safe and effective technique and that the nephrostomy catheter is responsible for an increase of postoperative morbidity. According to the results of our series, the tubeless technique does not provide any advantage, especially regarding postoperative morbidity. A critical review of the literature shows that nephrostomy catheter can be a victim of selection bias.
