Abstract

Introduction

Diabetic patients have a higher tendency of developing all infections, especially infections of the genitourinary tract. In most cases, urinary tract infections (UTI) in diabetic patients are asymptomatic. The aim of this study was to compare the incidence and clinical and microbiological features of UTI between diabetic and non-diabetic patients.

Methods

In this prospective, comparative study, the incidence and clinical and microbiological features of UTI were compared between diabetic and non-diabetic patients via consecutive non-probability sampling technique. For every diabetic patient, one non-diabetic control was included. All patients were screened for UTI through a midstream urinary sample. Their demographic characteristics, clinical profile, and urinary microscopy were compared. Data were entered and analyzed using SPSS version 22.0.

Results

In the diabetes group, 35/256 (13.67%) patients had culture-positive UTI as compared to 18/250 (7.2%) in the non-diabetic group. Diabetic group had twice the risk of UTI ($p = 0.01$; odds ratio [OR]: 2.04; confidence interval [CI]: 1.12, 3.71) and female gender in the diabetic group had a risk of almost five times ($p = 0.01$; OR: 4.93; CI: 1.12, 20.16) that of the non-diabetic group. In the diabetic group, 51.4% patients were asymptomatic as compared to 5.6% in the non-diabetic group ($p = 0.03$; OR: 7.79; CI: 0.92, 66.18). *E. coli* was the most commonly identified microorganism in both groups. *Pseudomonas aeruginosa* was identified in 14% of diabetic cases and none in the non-diabetic.

Conclusions

UTIs are more frequent among diabetics. Asymptomatic bacteriuria is a more common entity in diabetic patients and does not require any treatment.

Introduction

Diabetes mellitus is associated with immune system dysfunction, which makes the affected individuals prone to repeated infections, especially infections of the genitourinary tract. Diabetic patients have more than twice the tendency of developing genitourinary tract infections [1]. The altered host responses in diabetic patients cause increased adherence of the microorganisms to the uroepithelial cells, granulocyte dysfunction, and altered intracellular calcium metabolism. This results in increased susceptibility of these individuals to develop urinary tract infections (UTIs) [2-3]. Another important pathology underlying the increased incidence of UTIs and recurrent UTIs in the diabetic population is diabetic bladder dysfunction. It affects more than half of the people with longstanding and poorly controlled diabetes. It includes storage problems as well as voiding problems [4]. Furthermore, some pathogens flourish well in high glucose environment [5].

UTIs may be symptomatic or asymptomatic [6]. The common symptoms include burning micturition, urgency, dysuria, cramping in the lower abdomen, mental irritability, back or flank pain, chill, nausea, fever, vomiting, fatigue, and weakness [7]. *Escherichia coli* (*E. coli*) is the prominent causative pathogen of UTI in both diabetic and non-diabetic populations, followed by coagulase-negative *Staphylococci* (COns), *Enterococcus* species (spp.), *Candida albicans*, and non-albicans *Candida* spp. [6,8]. It is very important to screen diabetic patients for UTI for timely diagnosis, complete treatment, and prevention of progression to renal complications and ultimately severe renal failure. However, there are controversies regarding the...
incidence, clinical pattern, and microbiology of UTIs in diabetic individuals as compared to those in non-diabetic ones [5]. Hence, this study was conducted to compare the incidence and clinical and microbiological features of UTIs between diabetic and non-diabetic patients. It would help assess the frequency of UTIs in the diabetic population and enable the diabetologists predict the clinical and microbiological patterns of UTI in their patients.

**Materials And Methods**

This prospective, observational, cross-sectional, comparative study was conducted from July 1, 2017 to February 28, 2018 in the outpatient department (OPD) of a general hospital in Pakistan. Ethical approval from the institute was acquired. Consecutive non-probability sampling technique was adapted. All patients of type II diabetes mellitus, of both genders and age 18 years and above, were recruited after informed consent. All patients were screened for UTI through a midstream 5-ml urinary sample. The presence of bacteria, positive leukocyte esterase, and white blood count (WBC) >5 per high power field (HPF) were taken as diagnostic for UTI. Pyuria was defined as WBC >10/HPF, and hematuria was defined as red blood cells >5/HPF. Urinary culture analysis, for identification of the pathogen, was performed only for patients who were found to be infective on urine microscopy.

Clinical and demographic characteristics included in the study were as follows: age, gender, and HbA1c for both groups. For the diabetic group, duration of diabetes, diabetes-related complications, and the presence of diabetic kidney disease were also noted. Patients who had taken antibiotics within the last two weeks for any reason were not included in this study. Patients with anatomical and neurologic urinary tract abnormalities, pregnant women, cases of complicated UTI (including pyelonephritis), and patients with acute and/or chronic renal failure were also excluded.

During the study period, 260 diabetic patients were recruited. For every diabetic patient, a non-diabetic patient was included. The non-diabetic control group was selected from the attendants of the diabetic group to align their sociodemographic characteristics. By the end of the study, there were 256 records in the diabetes group and 250 records in the non-diabetes group. Their data was managed using SPSS for Windows version 22.0 (IBM Corp., Armonk, NY). The mean and standard deviation were calculated for continuous variables such as age, duration of diabetes, and HbA1c levels. Frequency and percentages were calculated for categorical variables. The incidence of UTI was compared for the diabetic and non-diabetic groups. Chi-square was applied for comparison. P-value ≤0.05 was taken as significant. Odds ratio (OR) and confidence interval (CI) were calculated.

**Results**

Among 256 patients in the diabetic group, there were 112 (43.7%) males and 144 (56.3%) females. Their mean age was 56 ± 11 years. Non-diabetic patients were relatively younger with a mean age of 48 ± 12 years. There were more women (n = 156; 62.4%) than men (n = 94; 37.6%) in the non-diabetic group. Demographic and clinical characteristics of both study groups are compared in Table 1.
Patient Characteristics | Diabetic Group (n = 256) | Non-diabetic Group (n = 250)  
--- | --- | ---  
Gender | |  
Male | 112 (43.7%) | 94 (37.6%)  
Female | 144 (56.3%) | 156 (62.4%)  
Age in years | |  
Mean | 56 ± 11 | 48 ± 12  
Less than 40 years | 38 (14.8%) | 72 (28.8%)  
40-60 years | 115 (44.9%) | 87 (34.8%)  
Above 60 years | 103 (40.2%) | 91 (36.4%)  
Duration of diabetes in years | |  
Mean | 7.6 ± 3.8 |  
Less than 5 years | 78 (30.5%) | Not applicable  
5-10 years | 97 (37.8%) |  
More than 10 years | 81 (31.6%) |  
Diabetic complications (any) | |  
Yes | 118 (46.1%) | Not applicable  
No | 138 (53.9%) |  
Diabetes-related kidney disease | |  
Yes | 34 (13.3%) | Not applicable  
No | 222 (86.7%) |  
Glycosylated haemoglobin A1c (%) | |  
Mean | 7.8 ± 2.6 | 4.9 ± 1.2  
Less than 7% | 48 (18.7%) | 250 (100%)  
7%-8.5% | 134 (52.3%) |  
More than 8.5% | 74 (28.9%) |  

TABLE 1: Demographic and clinical characteristics of participants in the diabetic group (n = 256) and non-diabetic group (n = 250)

In diabetes group, 35 (13.67%) patients were identified with culture positive UTI as compared to 18 (7.2%) participants in non-diabetic group. In both groups, UTI was more common in female gender. Diabetic group had an overall twice risk of UTI (p = 0.01; OR: 2.04; CI: 1.12, 3.71) and female gender in diabetic group had a risk of almost five times (p = 0.01; OR: 4.93; CI: 1.12, 20.16) that of the non-diabetic group of developing urinary tract infection (Table 2).
TABLE 2: Incidence of urinary tract infection in the diabetic group (n = 256) and non-diabetic group (n = 250)

Almost 30% patients in the diabetic group with culture-proven UTI were asymptomatic as compared to only 5% in the non-diabetic group (p = 0.03; OR: 7.79; CI: 0.92, 66.18). There was no other significant difference between the presentations of UTI in the two groups, as shown in Table 3.

TABLE 3: Clinical and incidence of urinary tract infection in the diabetic group (n = 256) and non-diabetic group (n = 250)

E. coli was the most commonly identified microorganism in both diabetic and non-diabetic groups. P. aeruginosa was identified in 14% of diabetic cases. Other organisms included Klebsiella species and Enterobacter species (Table 4).

**Discussion**

This study compared the incidence of UTIs in demographically comparable groups of diabetic and non-diabetic individuals. There was an overall significantly higher incidence of UTIs in the diabetic group; these individuals had twice the risk as compared to non-diabetics. Females also showed a significantly higher incidence of UTIs in the diabetic group. Females had an overall five-time higher risk of developing UTI in the diabetic group. There were no stark differences in the clinical and microbiological profiles of these patients; however, the diabetic group showed significantly more patients with asymptomatic UTI.

In our diabetic sample of 651 culture-positive UTI, the frequency of $Pseudomonas$ was isolated from non-diabetic urinary samples and none from the diabetic population. Bashir et al. reported that 1% cases of $Pseudomonas$ were isolated, and Zahra et al. 6% cases of $Pseudomonas$ were isolated from non-diabetic urinary samples and none from the diabetic population. In a Sudanese diabetic sample, the frequency of UTI was 19.5%. Asymptomatic bacteriuria was present in 21% of these patients.

Asymptomatic pyuria was significantly more common in the diabetic group as compared to non-diabetic in this study (50% vs. 5.6%; $p = 0.05$). In an Indian study, asymptomatic bacteriuria was found in 40% of urinary samples in a diabetic population. Hematuria was reported in 4% of their samples, as compared to 5.7% in our diabetic samples. The most common isolate in their study was also E. coli. In a Sudanese diabetic sample, the frequency of UTI was 19.5%. Asymptomatic bacteriuria was present in 21% of these patients.

Clinical presentation of UTI in both groups was comparable in our study. Similarly, no significant difference was seen in the clinical presentation in Aswani et al. (5). Even the frequency of asymptomatic bacteriuria was similar (30%) in both diabetic and non-diabetic groups in their analysis (5). According to the Infectious Disease Society of America (IDSA) guidelines, diabetic patients should not be screened or treated for asymptomatic bacteriuria (19). When clinical signs are present, UTIs are to be treated as per the culture and sensitivity report.

**Conclusions**

The frequency of UTIs is higher in the diabetic population as compared to their non-diabetic counterparts.
UTIs are more common among females in both groups. Clinical presentation in the two groups is also similar. Asymptomatic bacteriuria is a more common entity in diabetic patients and does not require any treatment.
